Bulk water
Capillary
Water vapor

Assumption: no leakage
1. Roof
2. WRB in walls
3. Foundation waterproofing

Capillary transfer is trivial in the absence of a bulk source

One aim: manage permeances and their arrangements to avoid moisture problems
One problem: Mold growth within the envelope (not surface)
Tools: steady-state and transient hygrothermal analysis, ASHRAE Standard 160, ISO 13788
Assumptions

• The walls and roofs comply with the thermal requirements found in the document.

• The walls and roofs are designed and constructed to be sufficiently airtight that the building can meet the airtightness requirements found in the document. For that reason, water vapor transport due to air movement through the building envelope assembly is ignored.
  • If water vapor transport due to air movement is to be included, the flows shall be calculated using the parallel permeance methods described in ASHRAE Handbook [ref].

• There is no leakage of liquid water into the assembly.

• The only damage to components in the building assembly that is considered in this section is mold growth on surfaces other than the exposed interior and exterior surfaces of the assembly.
  • Table below lists all common forms of damage to wall and roof assemblies, and explains why and how the form of damage is included or excluded from consideration in this section.
  • With the adoption of Addendum e, ASHRAE 160 has become a satisfactory method for estimating damage to assemblies due to mold growth on interior surfaces.

• The analysis used is one-dimensional. Two- and three dimensional effects are ignored.
Water vapor control specification

In fact, most building assemblies already comply with Standard 160. Common building assemblies can be tested by the standard, requiring only desktop modeling, and limiting temperature differences and humidity differences inside and out can be calculated. Building assemblies in tables to follow are deemed to comply with ASHRAE Standard 160.

If at-risk assemblies are shown to comply at a set of conditions, then lower-risk assemblies can be presumed to comply as well at those conditions. Variables for deemed-to-comply tables should include indoor climate (humidity) and outdoor climate (temperature).
Is “mold growth within the envelope (not surface)” the only problem within the scope of Water Vapor Control?
Moisture Control Guidance for Building Design, Construction and Maintenance
1. Surface. High humidity

2. Cool wall. High humidity

3. High humidity. Loose tile
4. Corrosion. Capillary water

Figure 1-4 Corrosion of galvanized fluted steel floor deck. The floor is at grade level. The source of the water is rainwater seepage.

5. Thermal bridge. High humidity

Figure 1-5 Corrosion of structural steel in a ceiling cavity in a cold climate. The steel extends into the exterior wall assembly. During cold weather, the steel near the wall is chilled by cold outdoor air. The building is humidified, and condensation from high indoor humidity provides the moisture that rusts the cold steel.

6. Wind-driven rain. Exterior paint

Figure 1-6 Blistering paint on split face concrete block. Wind-driven rain is the source of moisture contributing to the damage. Water wicks into the concrete masonry unit (CMU) through pin holes in the paint. The sun drives water vapor through the CMU. The assembly cannot dry to the interior because low-vapor-permeability foam board, taped at the joints, insulates the interior surface of the wall. The wall remains saturated throughout the spring, summer and fall. The same paint on areas of the wall sheltered from sun and rain shows no damage.
7. Mold behind wall Covering. Air leakage In walls.

8. Rainwater. Peeling paint

9. Seepage

11. Flood water. Gypsum damage.

12. Water beneath slab.

</tbody>
</table>
No water leakage in the building?

Roof must work, like a roof

Walls must have a Weather-Resistive Barrier
- ASHRAE Standard 160 allows 1% leakage across the WRB

Foundations must have a water barrier
- Basement walls must have dampproofing membrane and water management system
- Crawl spaces must have a ground cover
- Slabs must have a low-permeance membrane beneath the concrete
- Basement water problems are almost always associated with failure of the water management system.
Foundation water management system

Water management in foundations consists almost entirely of liquid water management and capillary water management. Vapor management plays a minor role. Liquid water management rarely relies on a single element, but instead includes several elements in series, each of which may be expected to be less than perfect. Liquid water management may occur at several levels:

• Gutter and downspout configuration to keep water away from the foundation,
• Sloping of soil surface away from the building
• “Flashing“ the building into the soil so that surface water close to the building is directed away from the soil in contact with the foundation
• Drainage of surface water downward so it cannot apply a head of liquid water to the foundation walls,
• Collection tiles at the base of the building, leading to daylight, to storm drains or to sump pumps,
• **Waterproofing** (membrane, coating, expansive clays) applied to walls.
• Coatings to resist capillary flow applied to the footing/wall joint, or to the insides of foundation materials
• Collection methods for rising ground water, together with discharge of collected water.
• Ground covers (ideally sealed against water leakage and evaporation) in crawl spaces.
• Low permeance membranes beneath slabs.
• Isolation of the building from the foundation space
Water control for foundations
Attic ventilation

- In sloped roof construction, the insulation may be placed at the ceiling plane or at the roof plane. In either case, the air barrier should be located contingent to or integral with the thermal barrier.

- For ceiling-insulated thermal barriers, with high levels of insulation and with low-airflow ceilings, the presence or absence of attic ventilation makes little difference in water vapor control. **Attic ventilation carries an energy penalty and a resilience (wind and fire storm resistance) penalty.**

- Low-slope roofs which comply with Standard 160 typically use high moisture-resistance materials in the assembly. They are not vented.

- Sloped roofs with the thermal barrier placed within the roof assembly should be designed to comply with Standard 160 without reliance on ventilation. Achieving useful ventilation is difficult in simple roofs, and is practically impossible in roofs with other than simple geometry: hips, valleys, sloped and low-slope adjacencies, long lengths.
Freeze-thaw?

1. Is there a stand-alone freeze-thaw problem?
   - A freeze-thaw problem where all water comes from the inside and none comes from the outside?
   - Answer: no. The water in freeze-thaw comes from exposure, not flow.

2. Will permeances and their arrangements make a difference?
   - No.

3. If it’s 100% exposure, how do we solve the problem?
   - Manage exposures.

4. Doesn’t low temperature, thanks to interior insulation, make it worse?
   - Yes.
   - But imagine consigning a building to perpetual fuel consumption, based on your professional opinion that, in the absence of that consumption, the building will collapse. Can’t you imagine alternatives?
Field Monitoring and Simulation of a Historic Mass Masonry Building Retrofitted with Interior Insulation

Student Member ASHRAE

ABSTRACT

Load-bearing masonry buildings are a significant portion of the existing building stock, and there is a great deal of interest in adding thermal insulation to the walls of these structures. Exterior insulation provides the ideal conditions for building durability; however, many buildings cannot be retrofitted with insulation on the exterior for reasons such as historic preservation.
The measured data from this mass masonry building retrofitted with interior insulation indicates that the masonry wall experiences colder temperatures than uninsulated walls, as would be expected. Monitoring also indicates that the insulated wall experiences higher moisture contents; however, this might reflect both the insulation retrofit and rain exposure at the sensor location. In addition, the moisture measurements in the walls varied in nominally identical wall sections: some sensors measured seasonally steady moisture levels, while others measured wetting responses consistent with driving rain events, followed by drying in warmer/drier conditions.

Hygrothermal simulations of the wall assemblies show good correlation to temperature measurements; however, there were significant differences in the moisture responses. These differences may be due to sensor response, driving rain exposure, or anomalies within the mass masonry wall assembly (redistribution of moisture due to voids and cracks).

The hygrothermal simulations indicate a low risk of freezethaw damage, based on predicted brick moisture content levels and insulation levels. The installed sensors cannot resolve moisture contents in the high range (critical degree of saturation or Scrit) at which freeze-thaw damage occurs. However, these instruments indicate seasonal trends of wetting and drying.

Although the measured moisture levels were highly variable, and did not have high correlation with modeled results, it still may be useful to install instrumentation in other mass masonry buildings retrofitted with interior insulation to gain understanding of the variables that affect the results. Direct measurement of driving rain on the instrumented wall surface may reduce the uncertainty.

In future work on insulated mass masonry buildings, the assessment of water shedding and water concentrations on the exterior face and improving the water shedding details are the key requirements before considering interior insulation. Material property testing and hygrothermal simulations are useful for assessing the risk in a more rigorous manner, based on localized climate and assembly type. Site load monitoring (driving rain, climate conditions) and building assembly monitoring are also useful tools—albeit more costly, intrusive, and time consuming—to consider in critical cases.
Condensation

“Condensation” is not listed as form of moisture damage to walls and roofs. This is because:

The building materials considered here (almost entirely) are sorptive. That is, the building materials here do not show the formation of droplets condensed from adjacent air cavities containing water vapor.

• Instead, sorptive materials will absorb or adsorb water, they will become heavier or lighter with daily and other cycling, and this weight change or moisture uptake is natural, not a cause for concern.

• Moisture uptake in sorptive materials becomes a concern when the wetness of the materials, together with the temperature of the surface, permits mold to grow. Mold growth is precisely the focus of ASHRAE 160, which serves as the basis for this specification.
Student:

“No, no, no. Condensation is when two lines cross on a dewpoint chart.”

Professor (me):

“Lines never cross on a dewpoint chart.”

Audience (you):

“huh?”
Larry V. Teesdale

Senior research engineer at US Forest Products Laboratory, Madison WI.

Smart guy.
Teesdale, “Condensation in walls and attics”, US FPL Report 1937
Test results. Note: the cavity vapor pressure is DETERMINED by the sheathing temperature.

Common wisdom: “If the lines cross, you have condensation.” Actual fact: The lines don’t cross.

This is exactly consistent with ASHRAE Handbook Fundamentals, Glaser method.

Summary

1. With assumptions regarding insulation, airtightness and water tightness,…
2. Single specification: compliance with ASHRAE 160
3. Deemed-to-comply tables for simplicity
4. Discussed:
   1. Moisture problem types and dependence on water vapor control
   2. “Condensation”
   3. Foundations
   4. Freeze-thaw
   5. Attic ventilation
To-do list

1. Number of years for d-t-c tables? 3 yrs? 10 yrs?
2. Maps or tables or formulas for d-t-c?
3. Critical plane identification
4. Cooling season problems?
5. Coordinate with ISO 13788
